

Weak moral motivation leads to the decline of  
voluntary contributions

Charles Figuières, David Masclet and Marc Willinger

December 5, 2010

## **Abstract**

We develop a model that accounts for the decay of the average contribution observed in experiments on voluntary contributions to a public good. The novel idea is that people's moral motivation is "weak". Their judgment about the right contribution depends on observed contributions by group members and on an intrinsic "moral ideal". We show that the assumption of weakly morally motivated agents lead to the decline of the average contribution over time. The model is compatible with persistence of over-contributions, variability of contributions (across and within individuals), and the "restart effect". Furthermore, it offers a rationale for conditional cooperation.

Keywords: Conditional cooperation, voluntary contributions, moral motivation, experiments on public goods games.

# 1 Introduction

Several experimental studies have documented strong empirical regularities in linear public goods experiments including (1) the fact that people contribute more than predicted by the standard theoretical model; and (2) that average contribution declines steadily over time when the game is repeated under a finite horizon.<sup>1</sup> Over the last 15 years, a huge amount of literature has been devoted to the puzzling finding that subjects over-contribute with respect to their Nash contribution. Much fewer attempts have been made to explain the decline of the average contribution observed in most linear public goods experiments. Three major explanations have been proposed : learning, strategic play and heterogeneous social preferences.

According to the learning hypothesis over-contributions in early rounds arise because subjects are confused and make errors. Over time they realize that they could earn more by over-contributing less, and adjust their current contribution accordingly. However, available evidence about learning suggests that it plays a limited role in the decay<sup>2</sup>. Furthermore, the learning hypothesis seems incompatible with the “restart effect” found by Andreoni (1988)<sup>3,4</sup>.

---

<sup>1</sup>See Ledyard (1995) for a review of this literature published prior to 1995; See also Andreoni, 1995; Croson, 1996; Gaechter & Fehr, 1999; Keser & van Winden, 2000; Fehr & Gaechter, 2000; Masclet et al., 2003; Carpenter, 2007; Sefton et al., 2007; Herrmann et al., 2008.

<sup>2</sup>Neugebauer et al. (2009a) found that repetition without feedback about previous group contributions has no effect on average contribution which seems to suggest that there is no learning by introspection. Houser & Kurzban (2002) found a sharper decay when a single subject plays against a computer program. Since overcontribution did not vanish the authors conclude that more than 50% of the overcontribution is due to confusion.

<sup>3</sup>Andreoni observed that after an unexpected restart, the average contribution of the first restart period is equal to the average contribution of the first period of the initial sequence.

<sup>4</sup>Anderson et al. (2004) developed a theory of learning based on quantal response. In their model the dynamic process of individual contributions follows the Fokker-Planck equation and converges to the logit equilibrium distribution of contributions. Despite its mathematical elegance, the model has two limitations : first, it does not explain why contributions are sensitive to the remaining number of periods as observed in partner sessions , and second, it assumes that players are able to best-respond to

The hypothesis of "strategic play" is based on the idea that players take into account future interactions when choosing their current contribution. Therefore, in early periods they have an incentive for establishing a cooperative reputation, by making a large contribution. The justification of the strategic hypothesis is based on the "crazy player" assumption (Kreps et al., 1982), or equivalently on the lack of common knowledge of rationality. If (rational) players believe that there is a crazy player in the group who contributes positively in period 1, it becomes rational for them to play a trigger strategy in early periods and to mix over the strategy space as the repeated game approaches the final period<sup>5</sup>. Andreoni (1988) offered the first test of the reputation hypothesis by comparing the average contributions of partner groups with stranger groups. Since there is no incentive to develop a cooperative reputation among strangers, one should observe higher over-contributions in partner-groups than in stranger-groups, especially in early periods of the repeated game. Surprisingly, Andreoni (1988) found that strangers contribute more than partners, that the difference in average contribution increases over time, and that complete free-riding is significantly more frequent in the partner treatment. These findings seem to undermine the reputation hypothesis as a plausible explanation of the decay in average contributions.<sup>6</sup>

The third explanation is rooted in social preferences, more precisely on conditional cooperation, i.e. the fact that people choose to cooperate, depending on previously observed decisions of others or on beliefs about their decisions (e.g. Keser & van Winden, 2000; Fischbacher et al., 2001; Croson, 2007; Fischbacher & Gaechter, 2010). Up to recently, reciprocity theories tended to attribute the decay to preference heterogeneity : 

---

the stochastic distribution of other players' contributions by choosing a stochastic distribution over their strategy space, which requires a high degree of sophistication for each player to form expectations about other players' choice probabilities.

<sup>5</sup>Strategic play is compatible with the fact that most subjects over-contribute in early periods and switch to their Nash contribution at some later period (see e.g. Isaac et al. (1994), Laury (1997), Keser & van Winden (2000)). The evidence of a slower decay in longer games (Isaac et al. 1994) is compatible with the strategic hypothesis.

<sup>6</sup>The evidence is mixed however (see Andreoni & Croson, 2008).

reciprocal cooperative players are mixed with selfish agents who free-ride on others' contributions. A reciprocal player who observes that his contribution is above (below) the group average, or who expects others to contribute less (more), will reduce (increase) his contribution, and therefore the mean contribution may decline. But heterogeneity per se is neither a necessary nor a sufficient condition for the decline<sup>7</sup>. What is meant here is that, although heterogeneity of a certain kind is sufficient to produce the decay in average contribution, not any kind of heterogeneity could do the job. Heterogeneity can either reinforce or attenuate the tendency for the decline, but is not the central driving force of the process. According to Fischbacher & Gaechter (2010) imperfect conditional cooperation is the main driving force behind the decay : "Many people's desire to contribute less than others, rather than changing beliefs of what others will contribute over time". There is strong experimental evidence for such imperfect reciprocity (Fischbacher & Gaechter, 2010, Fischbacher et al., 2001) or selfishly-biased reciprocity (Neugebauer et al., 2009). Our reading of this literature is that imperfect reciprocity is the main driving force behind the decay, while learning and strategic behavior reinforce this tendency.

In this paper, we propose a new model of behavior, compatible with the imperfect conditional cooperation hypothesis, and which accounts for the decline of average contribution. Precisely, it is based on the idea that agents set their moral target by relying on two dimensions : a "morally ideal contribution" (see Brekke et al., 2003, Nyborg, 2000)

---

<sup>7</sup>It is not necessary because if reciprocators contribute a little less than the observed (or expected) average contribution, decay can arise even in a population composed exclusively of non-selfish agents. A population of identical non-selfish agents, but slightly selfishly oriented, is enough to provoke the decline.

To see why it is not sufficient, let us define a perfect reciprocator as a player who matches the average group contribution of the previous period. Consider a case involving only two players : a perfectly reciprocal player and an unconditional player who contributes a fixed amount in each period. As the game is repeated the contribution of the reciprocal player converges to the fixed contribution of the unconditional player, with a slope that depends on the initial contribution of the reciprocator. Hence the average contribution could increase! The example can be easily extended to any mixed population of any finite size composed of perfect reciprocators and unconditional players. Adding noisy players who contribute a random amount does not prevent that the mean contribution either decays or increases.

and the observed contributions of others. The assumption that people rely on a morally ideal contribution is defended by commitment theories (see e.g. Croson 2007). Based on Kantian reasoning, these theories assume that individuals make "unconditional" commitments to contribute to the public good. Our originality is to assume that for most people such commitments are weak in the sense that they are sensitive to the observation of others' actions. In a contribution context, individuals might therefore be tempted to revise their preferred contribution after observing others' contributions. The extent of such a revision typically varies across individuals : strongly morally motivated agents will closely stick to their ideal contribution, while weakly motivated agents are prone to revise their morally ideal contribution whenever they observe a gap between their own and others' contributions. Our idea is that most people are of the "mixed" type, i.e. their actual contribution is the outcome of a deliberative process through which their preferred contribution is balanced against others' observed average contribution. The assumption of weakly morally motivated agents offers a possible justification for imperfect reciprocal behavior that we call *action-based reciprocity* : individuals' ideal contribution is sensitive to others' observed contributions. Alternatively, individuals might also decide about their contributions by relying on their expectations about others' contributions (*belief-based reciprocity*). However, such beliefs are themselves revised according to observed contributions.

While our model is primarily designed to explain the decline of average contribution we show that it is compatible with the other empirical regularities observed in experiments on voluntary contributions to a public good. We summarize them as follows : a) subjects contribute about half of their endowment in the first period, b) over-contribution remains significant in the final period, c) individual contributions exhibit high variability over time, d) most subjects adjust their contribution from one period to the next. These regularities have been found in experimental games either with a corner solution or with interior equilibria, except that stylized fact a) should be read "subjects contribute mid way between the equilibrium contribution and the socially optimum contribution" (see Sefton & Steinberg, 1996, Laury & Holt, 1998). Finally, our model is also compatible with

the restart effect (Andreoni, 1988, Croson, 1996) and accounts for the observation that the decay occurs at a slower pace when the length of the game is extended (Isaac et al., 1994).

Section 2 introduces the concept of weak moral motivation and shows its implications for the dynamics of average contributions in a simple linear public good model with myopic agents. Section 3 extends the results to non-myopic agents. Our assumptions and results are discussed in section 5 and contrasted with other models, with a particular attention to Kandori (2002), Klumpp (2005) and Ambrus & Pathak (2007) that are closely linked to our idea. Section 6 concludes.

## 2 Weak moral motivation and voluntary contributions

Consider  $n$  agents, indexed  $i = 1, \dots, n$ , who can contribute voluntarily to a public good. Each of them has an endowment  $w_i$ , which he can split between his contribution to the public good,  $x_i$ , and the consumption of private goods,  $w_i - x_i$ . Using the notation  $x_{-i} = \sum_{j \neq i} x_j$ , the cardinal representation of agents' preferences with moral motivation is :

$$U^i(x_i, x_{-i}, \hat{x}_i) = w_i - x_i + \beta_i(x_i + x_{-i}) - v_i(x_i - \hat{x}_i) \quad . \quad i = 1, \dots, n, \quad (1)$$

where  $\beta_i \in ]0, 1[$  is the marginal utility from consuming  $G = x_i + x_{-i}$ , the public good<sup>8</sup>.

Agent  $i$ 's moral motivation is embodied in the function  $v_i(\cdot)$ , where  $\hat{x}_i$  stands for his moral obligation. Her loss of utility attached to any deviation from her moral obligation is

---

<sup>8</sup>The results of the present paper also hold when preferences are captured by quadratic utility functions:

$$U^i(x_i, x_{-i}, \hat{x}_i) = \alpha_i(w - x_i) - (w_i - x_i)^2 + \beta_i(x_i + x_{-i}) - \frac{v_i}{2}(x_i - \hat{x}_i)^2.$$

This family of functions, which allows for a dominant strategy equilibrium with strictly positive contributions, has been documented in the experimental literature by relatively few papers (Keser, 1996, Bracht et alii, 2008).

$v_i(x_i - \hat{x}_i)$ . This function is assumed to be convex. In addition two natural assumptions about  $v_i(\cdot)$  are as follows:

**Assumption 1**  $v_i(0) = 0$ ,  $v_i(x_i - \hat{x}_i) > 0$  iff  $x_i \neq \hat{x}_i$ .

**Assumption 2**  $v'_i(\cdot) \gtrless 0 \Leftrightarrow x_i - \hat{x}_i \gtrless 0$ .

The first assumption is obvious: a departure from one's moral obligation entails a loss of utility. The second assumption means that, starting from a situation where agent  $i$  contributes less (more) than her moral obligation, a marginal increase of  $x_i$  reduces (increases) her loss of utility.

We shall conceptualize the *weak moral motivation* of each agent as a combination of two logics : an autonomous logic and the logic of social influence. The autonomous logic is captured by an ideal, or "ethical", level of contribution noted  $x_i^* \geq 0$ . For instance, it could correspond to a Pareto optimal level of contribution, i.e. contributing  $w_i$  for each  $i$ . Such autonomous logic can be grounded on a Kantian Categorical Imperative, or on an unconditional commitment to a contribution (Laffont 1975, Harsanyi 1980). The second logic, our originality, captures social influences *via* the average contribution observed in the immediate past,  $\bar{x}_{t-1} \geq 0$ . The group contribution is publicly observed after each period. Each player can therefore compare his contribution to the average group contribution. Discovering that her own contribution differs from the group contribution eventually leads her to judge that the society is less (or more) deserving than she initially thought, and consequently to revise her moral obligation  $\hat{x}_i$ .

Accordingly we define *strong moral motivation* as an unconditional commitment to stick to one's ideal contribution. In contrast *weak moral motivation* refers to one's sensitivity to the observation of others' actions, which can lead to a revision of one's intrinsic morally ideal contribution.

While our definition is restricted to contributions in public goods games, the scope of the issue is much wider. Do moral ideals motivate people's decisions or are moral opinions

an ex-post rationalization largely dictated by social influences and circumstances? Our concept is also in keeping with the philosophical discussion about the *weakness of will* (referred to as *akrasia*, see Holton 2007), an over-readiness to abandon or revise one's moral resolution. Do people change their mind in the course of interactions with others or is their will insufficiently strong to overcome the cost of self-enforcing their moral judgement? We shall briefly come back to those questions in the conclusion.

Overall, the qualified moral obligation,  $\widehat{x}_{it}$ , is defined as a function of the aforementioned variables:

$$\widehat{x}_{it} = \begin{cases} x_i^*, & t = 0, \\ M^i(x_i^*, \bar{x}_{t-1}), & t = 1, 2, \dots \end{cases}$$

where function  $M^i(.,.)$  is discontinuous at  $t = 0$ , for there is no previous observations at that date that could be used to qualify the autonomous ethical level.

The moral obligation function satisfies the intuitive properties:

**Assumption 3**  $\frac{\partial M^i}{\partial x_i^*} = M_1^i \geq 0$ ,  $\frac{\partial M^i}{\partial \bar{x}_{t-1}} = M_2^i \geq 0$ ,

**Assumption 4**  $x_{it}^{\min} = \min\{x_i^*, \bar{x}_{t-1}\} \leq M^i(x_i^*, \bar{x}_{t-1}) \leq x_{it}^{\max} = \max\{x_i^*, \bar{x}_{t-1}\}$ .

Also, it is assumed that the aggregate qualified moral obligation is bounded above by the aggregate autonomous moral obligation:

**Assumption 5**  $\sum_i M^i(x_i^*, a) \leq \sum_i x_i^* = G^*$ ,  $\forall a \geq 0$ .

Assumption 5 plays a key role for the dynamics of contributions in the linear public good game. According to this assumption aggregate contributions cannot exceed the aggregate initial moral motivation. For instance, if  $x_i^* = w_i$  for all  $i$ , actual contributions are necessarily bounded by aggregate endowment. In a more general sense, Assumption 5 means that players' moral motivation is not grounded on utopia but on realism and feasibility. However, while Assumption 5 holds in aggregate, it needs not be true at individual levels, *i.e.*  $M^i(x_i^*, a) > x_i^*$  for some  $i$  and some  $a$  is a possibility. Assumption 5 is further discussed in Section 3.

**Example 1** *An illustration of a weak moral motivation function is the following:*

$$\begin{aligned}\widehat{x}_{it} &= (1 - \theta_i) x_i^* + \theta_i \bar{x}_{t-1} , & \theta_i \in [0, 1] , \\ &= x_i^* - \theta_i (x_i^* - \bar{x}_{t-1}) .\end{aligned}$$

*The weight  $1 - \theta_i$  may be interpreted as the "strength" of agent  $i$ 's moral motivation. If  $\theta_i = 0$  agent  $i$  has as strong moral motivation : he never deviates from his ideal contribution, whatever the observed average contribution by other members of his group. On the other hand, an agent for whom  $\theta_i$  is close to 1 will strongly revise her initial moral ideal, whenever her current contribution differs from the average group contribution. Assuming the above revision rule, a purely reciprocal player can be defined as a player for whom  $\theta_i = 1$ , while a unconditional free-rider is defined by  $\theta_i = 0$  and  $x_i^* = 0$ .*

If the contribution game is played only once, player  $i$  has a dominant strategy to contribute less than his moral motivation. He chooses  $x_i$  to solve :

$$\max_{x_i} w_i - x_i + \beta_i (x_i + x_{-i}) - v_i (x_i - x_i^*).$$

The first order condition gives :

$$-1 + \beta_i = v_i' (x_i - x_i^*)$$

At equilibrium the agent equalizes the marginal material cost of a contribution ( $\beta_i - 1$ ) to the marginal moral cost of a deviation from her moral ideal ( $v_i' (x_i - x_i^*)$ ), which implies that her actual contribution is less than her moral ideal :

$$x_i = x_i^* + (v_i')^{-1} (\beta_i - 1) < x_i^* ,$$

since  $\beta_i < 1$ ,  $(v_i')^{-1} (\beta_i - 1) < 0$ .

While our definition of weak moral motivation is related to a player's sensitivity to social influence, the above result shows that there is also a "private component" that drives agents' decisions. The latter can be thought as the temptation to deviate from the

moral ideal, in order to increase one's material utility. Indeed the individual chooses her optimum level of contribution by equalizing the marginal material cost of a contribution to the marginal moral cost of deviating from the moral ideal. As we shall see below, this selfish bias towards the material payoff plays also a role in the decay of average contributions.

### 3 Repeated play with myopic contributors

Assume now that the contribution game is played a finite number of periods. We assume that in each period players rely on their current updated moral motivation, which is determined by the observed average contribution of the previous period. A key assumption for this section, which is relaxed later in the paper, is that players do not take into account their influence on other players' future moral motivation when choosing their contribution. We define therefore, for each period of time, a Myopic Nash Equilibrium (MNE)<sup>9</sup> as a profile of contributions such that each agent's contribution maximizes his own current utility, given the other agents' contributions:

$$\max_{x_{it}} w_i - x_{it} + \beta_i (x_{it} + x_{-it}) - v_i (x_{it} - \hat{x}_{it}).$$

From the first order conditions, interior decisions solve:

$$-1 + \beta_i = v'_i (x_{it} - \hat{x}_{it}) , \quad \forall i, \forall t,$$

thus individual equilibrium contributions at period  $t$  are:

$$x_{it} = M^i (x_i^*, \bar{x}_{t-1}) + (v'_i)^{-1} (\beta_i - 1) , \quad \forall i .$$

The revision rule for the moral motivation naturally leads to an interpretation of *action-based* reciprocity: current period contributions are partly determined by past observed contributions (and partly by individuals' moral motivation). The revision rule can be easily adapted to capture *belief-based* reciprocity. If we substitute "others' average contribution

---

<sup>9</sup>This concept is not ours. In particular it has been used extensively in the literature on processes (see Drèze and De la Vallée Poussin, 1977, for instance).

in the previous period" by the "expectation about others' contributions". The revision rule becomes  $\hat{x}_{it} = M^i(x_i^*, \bar{x}_{it}^e)$ , where  $\bar{x}_{it}^e$  is agent  $i$ 's expectation of the average contribution of other players for period  $t$ . The interpretation is now that agent  $i$  determines her current contribution by taking into account her expectation about the (current) contribution of other players and her initial moral motivation. The two formulations do not fundamentally differ if we assume that individuals' expectations are positively related to their observed contributions of other group members, *i.e.* if  $\bar{x}_{it}^e = f(\bar{x}_{it-1})$ , with  $f'(\cdot) > 0$ . With this assumption we restrict our interpretation to action-based reciprocity.

**Proposition 1** *At a MNE, the level of public good is non increasing over time. If Assumption 5 is verified with a strict inequality, then the level of public good is strictly decreasing over time.*

**Proof.** The proof is established recursively. Note first that  $G_1 = \sum_i x_i^* + \sum_i (v_i')^{-1} (\beta_i - 1) \leq \sum_i x_i^*$  because  $\sum_i (v_i')^{-1} (\beta_i - 1) \leq 0$ . Then observe that  $G_2 = \sum_i M^i(x_i^*, \frac{G_1}{n}) + \sum_i (v_i')^{-1} (\beta_i - 1) \leq G_1$ , because  $\sum_i M^i(x_i^*, \frac{G_1}{n}) \leq \sum_i x_i^*$  by Assumption A<sub>5</sub>.

Assume the property  $G_t \leq G_{t-1}$  holds for  $t = 3, \dots, k$ , for some  $k$ . To complete the proof, it must be established that  $G_{k+1} \leq G_k$ . This is straightforward, for if the property is true until  $t \leq k$ , it follows that  $G_{k+1} = \sum_i M^i(x_i^*, \frac{G_k}{n}) + \sum_i (v_i')^{-1} (\beta_i - 1)$  is not larger than  $G_k = \sum_i M^i(x_i^*, \frac{G_{k-1}}{n}) + \sum_i (v_i')^{-1} (\beta_i - 1)$ , because each  $M^i(\cdot, \cdot)$  is an increasing function of its second argument and this argument has fallen,  $G_k \leq G_{k-1}$ .

To obtain the second claim of the proposition, repeat the same logic using strict instead of large inequalities. ■

Assumption 5 turns out to be crucial in explaining the decay of aggregate contributions. It can receive two justifications. First, the assumption is necessarily satisfied in period 1, since the selfish bias curbs downwards each individual's contribution with respect to her initial ideal contribution. Of course, this fact does not preclude that some players adjust their moral ideal upwards. Assumption 5 can therefore be thought in the following way : downwards adjustments by high-motivated agents always loom larger than upwards

adjustment by low-motivated agents. Second, and more generally, it is reasonable to set as an upper limit to the aggregate moral ideal. Budget constraints are an obvious reason. But more importantly, the fact that group interactions occurs only over a finite number of periods, sets a natural upper boundary on individual revised moral ideals, whenever these are influenced by social interactions.

We now turn to another important regularity in public good experiments, namely that in the last period of the finitely repeated game, subjects over-contribute significantly compared to the Nash prediction (see Holt & Laury, 2008). The dynamics of aggregate equilibrium contributions  $G_t = \sum_i x_{it}$  are:

$$G_t = \sum_i M^i \left( x_i^*, \frac{G_{t-1}}{n} \right) + \sum_i (v_i')^{-1} (\beta_i - 1). \quad (2)$$

The dynamic process in (2) can eventually reach a level of contribution equal to zero, the free-riding equilibrium in standard linear public good's games. To account for over-contributions in our framework, two additional assumptions on the moral motivation function are required : the first one stipulates that an increase of the previous level of public good has a less than proportional positive effect on the levels of weak moral motivations:

**Assumption 6**  $M_2^i \leq 1$ .

The second requires the moral motivation to be strong enough to induce a positive level of public good at a MNE even if the previous observable level was zero, i.e. even with an extremely adverse social influence.

**Assumption 7**  $\sum_i M^i (x_i^*, 0) \geq -\sum_i (v_i')^{-1} (\beta_i - 1)$ .

**Theorem 1** *Under Assumptions 5, 6 and 7, the sequence of public good levels converges to a unique positive interior level  $G^\infty \in ]0; \sum_i x_i^*[$ .*

**Proof.** Under Assumption 6, the right hand side of the dynamics (2) is a contraction. Therefore, according to Banach's fixed point theorem : *i*) the dynamics (2) has a unique steady state, *ii*) the sequence converges towards this steady state. Assumptions 5 and 6 respectively discard the zero and full contributions corner stationary points. ■

**Proposition 2** *Under Assumption 6, the higher the autonomous ethical level  $x_i^*$ , the higher the long run level of public good  $G^\infty$ .*

**Proof.** The long run level of public good solves

$$G^\infty = \sum_i M^i \left( x_i^*, \frac{G^\infty}{n} \right) + \sum_i (v_i')^{-1} (\beta_i - 1). \quad (3)$$

Using the implicit function theorem:

$$\frac{dG^\infty}{dx_i^*} = \frac{M_1^i}{1 - \frac{\sum_h M_2^h}{n}} > 0$$

under Assumption 6. ■

**Proposition 3** *Under Assumption 6, the higher the marginal utility of the public good  $\beta_i$ , the higher the long run level of public good  $G^\infty$ .*

**Proof.** Using (3) and the implicit function theorem again, one finds:

$$\frac{dG^\infty}{d\beta_i} = \frac{1}{\left(1 - \frac{\sum_h M_2^h}{n}\right) v_i''} > 0,$$

since in the denominator the first term between bracket is positive under Assumption 6 and the second term is also positive, for  $v_i(\cdot)$  is a convex function. ■

## 4 Forward-looking contributors

In this section we turn decisively away from the assumption of myopic agents. Instead we assume now agents who have extensive computing capabilities, based on full information. Each agent knows the utility functions of others, including their moral obligation function,

and knows that others know this, and everyone knows that everyone knows, etc. (complete information). This will allow us investigate how forward looking behavior affects the dynamics of average contribution. Forward looking players take into account the impact of their current contribution on other players' revised moral motivation in future periods, and are aware that other players try to influence their own future moral motivation. Such mutual influence, might eventually lead to an increase in average contributions. We show however that, under reasonable assumptions, the average contribution still declines over time.

Let  $T$  be the number periods during which agents interact and  $0 < \sigma \leq 1$  their common discount factor. We define players' intertemporal utility as :

$$\sum_{t=0}^T \sigma^t U^i(x_{it}, x_{-it}, \hat{x}_{it}) \quad , \quad i = 1, \dots, n,$$

where

- $U^i(x_{it}, x_{-it}, \hat{x}_{it}) = w_i - x_{it} + \beta(x_{it} + x_{-it}) - \frac{v_i}{2}(x_{it} - \hat{x}_{it})^2$ ,  $v_i$  a positive scalar,
- $\hat{x}_{it} = (1 - \theta_i)x_i^* + \theta_i \bar{x}_{t-1} = M^i(x_i^*, \bar{x}_{t-1})$ ,  $\theta_i \in [0, 1]$ .

We will consider a Markov perfect equilibrium (MPE) for this dynamic public good game. Reasoning backward, in the last period agent  $i$  takes as given  $x_{-iT}$  and solves:

$$\max_{x_{iT}} w_i - x_{iT} + \beta_i(x_{iT} + x_{-iT}) - \frac{v_i}{2}(x_{iT} - M^i(x_i^*, \bar{x}_{T-1}))^2.$$

He has a dominant strategy, configured by the average contribution inherited from the previous period:

$$x_{iT} = \frac{-(1 - \beta)}{v_i} + M^i(x_i^*, \bar{x}_{T-1}) \equiv g_{iT}(\bar{x}_{T-1}).$$

It is worth noting that

$$g'_{iT} = M_2^i(\cdot, \cdot) = \theta_i. \tag{4}$$

Those equilibrium strategies can be plugged back into the last period utility, giving each agent's *value function* for the last period:

$$V_T^i(\bar{x}_{T-1}) \equiv U^i \left( g_{iT}(\bar{x}_{T-1}), \sum_{j \neq i} g_{jT}(\bar{x}_{T-1}), M^i(x_i^*, \bar{x}_{T-1}) \right).$$

Moving backward to the before last period, each agent solves:

$$\max_{x_{iT-1}} \left\{ \begin{array}{l} w_i - x_{iT-1} + \beta_i (x_{iT-1} + x_{-iT-1}) - \frac{v_i}{2} (x_{iT-1} - M^i(x_i^*, \bar{x}_{T-2})) \\ + \sigma V_T^i \left( \frac{x_{iT-1} + x_{-iT-1}}{n} \right) \end{array} \right\}$$

The optimal decision  $x_{iT-1}$  cancels out the addition of several marginal effects:

i) as when agents are myopic, in the current period:

$$-1 + \beta_i - v'_i (x_{iT-1} - M^i(x_i^*, \bar{x}_{T-2})),$$

ii) but unlike the case of myopic agents, there is also a marginal effect on the next period

$\sigma \frac{\partial}{\partial x_{iT-1}} V_T^i(\bar{x}_{T-1})$ . This expression can be developed as follows:

$$\begin{aligned} \sigma \frac{\partial}{\partial x_{iT-1}} V_T^i(\bar{x}_{T-1}) &= \sigma \left[ \begin{array}{l} -g'_{iT} + \beta_i (g'_{iT} + \sum_{j \neq i} g'_{jT}) \\ -v'_i (x_{iT} - M^i(x_i^*, \bar{x}_{T-1})) (g'_{iT} - M^i_2(x_i^*, \bar{x}_{T-1})) \end{array} \right] \frac{\partial \bar{x}_{T-1}}{\partial x_{iT-1}}, \\ &= \sigma \left[ -g'_{iT} + \beta_i \left( g'_{iT} + \sum_{j \neq i} g'_{jT} \right) \right] \frac{1}{n}, \\ &= \frac{\sigma}{n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right]. \end{aligned}$$

This second effect is the *discounted marginal impact of the current decision on future payoffs*, and it is channelled by the *discounted marginal value of the average contribution*. It explains the difference between the myopic and farsighted behaviors. Note that this difference owes nothing to the next period deviation from the moral motivation. Indeed, a marginal increase of  $x_{iT-1}$  has an impact on the next period moral motivation equal to  $\theta_i dx_{iT-1}$  but this increase is exactly offset by the next period optimal contribution, as noticed from (4), leaving the gap  $x_{iT} - M^i(x_i^*, \bar{x}_{T-1})$  unchanged. The difference only goes through the effect on the last period self-centered part  $w_i - g_{iT}(\bar{x}_{T-1}) + \beta_i (g_{iT}(\bar{x}_{T-1}) + \sum_{j \neq i} g_{-iT}(\bar{x}_{T-1}))$ .

Overall, the first order conditions are:

$$-1 + \beta - v'_i (x_{iT-1} - M^i(x_i^*, \bar{x}_{T-2})) + \frac{\sigma}{n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] = 0, \quad \forall i.$$

Hence, the best (dominant) response for each agent is:

$$\begin{aligned} x_{iT-1} &= -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] + M^i(x_i^*, \bar{x}_{T-2}), \quad (5) \\ &\equiv g_{iT-1}(\bar{x}_{T-2}). \end{aligned}$$

Observe again that:

$$g'_{iT-1} = M_2^i(\cdot, \cdot) = \theta_i.$$

Each agent's value function for the before last period is then:

$$\begin{aligned} V_{T-1}^i(\bar{x}_{T-2}) &\equiv U^i \left( g_{iT-1}(\bar{x}_{T-2}), \sum_{j \neq i} g_{jT-1}(\bar{x}_{T-2}), M^i(x_i^*, \bar{x}_{T-2}) \right) \\ &\quad + \sigma V_T^i \left( \frac{\sum_{h=1}^n g_{hT-1}(\bar{x}_{T-2})}{n} \right) \end{aligned}$$

Recursively it is possible to construct the agents' value functions for each date. There is no conceptual difficulty in this exercise but it is tedious and relegated to the Appendix. The important piece of information is that the individual problems at date  $T-t$  generically read as:

$$\max_{x_{iT-t}} \left\{ w_i - x_{iT-t} + \beta_i (x_{iT-t} + x_{-iT-t}) - v_i (x_{iT-t} - M^i(x_i^*, \bar{x}_{T-t-1})) + \sigma V_{T-t+1}^i \left( \frac{x_{iT-t} + x_{-iT-t}}{n} \right) \right\}.$$

And, using the notation  $\Lambda = \frac{\sigma}{n} \sum_{h=1}^n \theta_h = \sigma \bar{\theta} < 1$ , the dominant strategy  $t$  periods before the last can be written generically:

$$\begin{aligned} x_{iT-t} &= -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=0}^{t-1} \Lambda^h + M^i(x_i^*, \bar{x}_{T-t-1}), \quad (6) \\ &\equiv g_{iT-t}(\bar{x}_{T-t-1}). \end{aligned}$$

It will also prove useful to write the strategy at date  $s$  (i.e.  $s$  periods after the beginning):

$$\begin{aligned} x_{is} &= -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=0}^{T-s-1} \Lambda^h + M^i(x_i^*, \bar{x}_{s-1}), \quad (7) \\ &\equiv g_{is}(\bar{x}_{s-1}). \end{aligned}$$

Regardless of the direction in which time is counted, at the first period equilibrium decisions are:

$$\begin{aligned} x_{i0} &= -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=0}^{T-1} \Lambda^h + x_i^* , \\ &= g_{i0}(x_i^*) . \end{aligned} \quad (8)$$

We are now in a position to investigate whether those contributions could decline over time.

**Assumption 8** *Assume that:*

$$\begin{aligned} -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=0}^{T-1} \Lambda^h &\leq 0, \\ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j &\geq 0. \end{aligned}$$

Those two conditions on parameters are met for instance when agents value sufficiently the public good ( $\beta$  is large enough) and discount heavily the future ( $\sigma$  small enough). It can then be established:

**Theorem 2** *Under assumption 8, the MPE is characterized by non increasing contributions over time.*

**Proof.** Observe first that  $x_{i0} \leq x_i^* \forall i$ , by the first inequality in Assumption  $A_8$ , hence  $M^i(x_i^*, \bar{x}_0) \leq x_i^* \forall i$ . Then, we also have:

$$x_{i0} - x_{i1} = \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \Lambda^{T-1} + (x_i^* - M^i(x_i^*, \bar{x}_0)) \geq 0, \forall i,$$

since, by the second inequality in 8 the first term in the right hand side of the above expression is positive and, as seen above  $x_i^* - M^i(x_i^*, \bar{x}_0) \geq 0$ . Repeating the comparison of successive contributions, one immediately sees that  $x_{it}$  is non increasing over time. ■

From (8), when the horizon grows large ( $T \rightarrow \infty$ ), this first equilibrium decisions tend to:

$$x_{i0} = -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \frac{1}{1-\Lambda} + x_i^*.$$

Similarly, considering that period  $t$  is the first one, and letting the time horizon go to infinity, it is easy to see that the dominant strategies become stationary feedback rules:

$$\begin{aligned} x_{it} &= -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \frac{1}{1-\Lambda} + M^i(x_i^*, \bar{x}_{t-1}), \\ &\equiv g_i(\bar{x}_{t-1}), \quad \forall i. \end{aligned} \quad (9)$$

Clearly, under Assumption 8, the property of non increasing contributions carries over to the case of an infinite horizon.

We examine now the relevance of our model to account for two additional empirical facts : the restart effect and the softening of the decay as the horizon becomes longer.

Let us formalize a restart has follows : the duration of the game is first announced to be of  $T/2$  periods, then at date  $T/2$  there is a surprise restart announcement, according to which agents will play a further  $T/2$  periods after date  $T/2$ . There is a restart effect if the contributions at date  $\frac{T}{2} + 1$  with the restart announcement,  $x'_{i\frac{T}{2}+1}$ , are larger than the contributions at date  $T/2$  without the announcement,  $x_{i\frac{T}{2}}$ .

Without the surprise restart announcement, according to (6) or (5) at date  $T/2$  agents would contribute:

$$x_{i\frac{T}{2}} = -\frac{(1-\beta)}{v_i} + M^i(x_i^*, \bar{x}_{\frac{T}{2}-1}).$$

With the restart announcement made at date  $T/2$ , agents treat the problem as if they were engaged in a new  $\frac{T}{2}$ -period game, with an initial moral motivation  $M^i(x_i^*, \bar{x}_{\frac{T}{2}-1})$ , so their contribution in the next period of this new sequence (at date  $T/2 + 1$ ) is going to be:

$$x'_{i\frac{T}{2}+1} = -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=0}^{\frac{T}{2}-1} \Lambda^h + M^i(x_i^*, \bar{x}_{\frac{T}{2}}).$$

Next consider the difference:

$$\begin{aligned}
x'_{i\frac{T}{2}+1} - x_{i\frac{T}{2}} &= \frac{\sigma}{v_i n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=1}^{\frac{T}{2}-1} \Lambda^h \\
&\quad + M^i \left( x_i^*, \bar{x}_{\frac{T}{2}} \right) - \left[ + M^i \left( x_i^*, \bar{x}_{\frac{T}{2}-1} \right) \right] , \\
&= \frac{\sigma}{v_i n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=1}^{\frac{T}{2}-1} \Lambda^h \\
&\quad + \theta_i \left[ \bar{x}_{\frac{T}{2}} - \bar{x}_{\frac{T}{2}-1} \right] .
\end{aligned}$$

Hence

$$x'_{i\frac{T}{2}+1} > x_{i\frac{T}{2}} \Leftrightarrow \frac{\sigma}{\theta_i v_i n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=1}^{\frac{T}{2}-1} \Lambda^h > \bar{x}_{\frac{T}{2}-1} - \bar{x}_{\frac{T}{2}} .$$

Observe that, under Assumption 8, the right hand side of the above inequality is positive (because contributions are decreasing) and bounded. Indeed, the average contribution necessarily falls in the interval  $[0, w_i]$ , therefore  $0 \leq \bar{x}_{\frac{T}{2}-1} - \bar{x}_{\frac{T}{2}} \leq w_i$ . By contrast, if  $v_i$  approaches zero, the left hand side of the inequality tends to infinity. Thus:

**Proposition 4** *Under Assumption 8, there exists values of parameters  $v_i$  of the weak moral motivation functions such that a restart effect occurs.*

How can our hypothesis of weak moral motivation explain why the speed of decay differs according to the length of the game? Consider a decreasing sequence of contributions,  $x_{is+1} < x_{is}$ ,  $s = 0, 1, \dots, T$ . Using (7), the speed of change in contributions at date  $s + 1$ ,  $S_{s+1}$ , can be expressed explicitly (see appendix 5) :

$$\begin{aligned}
S_{s+1} &\equiv x_{is+1} - x_{is} < 0 \\
&= -\frac{\sigma}{v_i n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \Lambda^{T-s-1} + M^i(x_i^*, \bar{x}_s) - M^i(x_i^*, \bar{x}_{s-1}) .
\end{aligned}$$

The above expression shows that the length of the horizon  $T$  can have two effects on the speed  $S_{s+1}$  : a direct effect that is captured by the first term, and an indirect effect that corresponds to the difference  $M^i(x_i^*, \bar{x}_s) - M^i(x_i^*, \bar{x}_{s-1})$ . The direct effect corresponds

to the marginal impact of the horizon on the *discounted marginal value of the average contribution*. Clearly the larger the horizon, the lower the absolute value of this negative number, therefore the lower the speed, all other things equal.

Using the notation  $\bar{x}_s^T$  for the average contribution when the total number of periods is  $T$ , the second effect can be rewritten :  $M^i(x_i^*, \bar{x}_s^T) - M^i(x_i^*, \bar{x}_{s-1}^T) = \theta_i(\bar{x}_s^T - \bar{x}_{s-1}^T)$ . It corresponds to the impact of the horizon on the *marginal change of the non autonomous part of the weak moral motivation*. It depends in particular on how the change of the horizon modifies the sequences of averages  $\bar{x}_0^T, \bar{x}_1^T, \dots$ . The indirect effect is ambiguous : it could either reinforce or counteract the direct effect, resulting either in a slower or larger speed when the horizon is larger<sup>10</sup>. However, under the assumption of identical agents, the ambiguity vanishes :

**Proposition 5** *In the contribution game with  $n$  symmetric agents and decreasing contributions, the longer the horizon, the slower the decay.*

**Proof.** Appendix B. ■

## 5 Discussion

Three attempts to explain the decline in contributions to public goods are closer to ours than any others. These are Kandori (2002), Klumpp (2004) and Ambrus & Pathak (2010).

The model proposed by Kandori (2002) is based on the general idea that the decline is generated by the erosion of norm and morale. This idea is very close to our concept of weak moral motivation, although the author takes a radically different modeling approach. The dynamics is introduced in two ways. First, individuals revise their current effort with respect to the previous period median, which determines therefore a new current median. Second, in each period there is a small probability (the mutation rate) for

---

<sup>10</sup>We analyzed a numerical example with two agents, one with a relatively strong preference for the present ( $\sigma \simeq 0$ ). For this agent the direct unambiguous effect is (almost) neutralized, and the speed of change of his contributions can be faster indeed.

each player to change his behavior. He ends up choosing randomly, i.e. each level of effort is chosen with equal probability. The author shows that the evolutionary stable equilibria are characterized by declining median effort. Since only the symmetric players' case is considered, this model does not account for variability in individual contributions. Also, since players are assumed to behave myopically expectations-driven decay is precluded. Finally, the hypothesis that players adjust their effort with respect to the median effort, requires that each player observes all other players' individual efforts, a context that does not fit most of the available experimental data on voluntary contributions.

Ambrus & Pathak (2010) consider a mixed population of players, which consists of selfish and reciprocal types. While the selfish players have homogenous preferences, there is heterogeneity among reciprocal types, which is captured by reciprocity functions. The dynamics of the model is generated by the behavior of selfish players who have an incentive to contribute large amounts in early periods because of their influence on future contributions of reciprocal types. The incentive to cooperate of selfish players depends on the number of remaining periods in the repeated game. As the end of the game approaches, the selfish players switch to their Nash contribution of the one-shot game, i.e. zero contribution. The authors assume a continuous strategy space (players can contribute any real number between 0 and 1). The key assumption for the decline is common knowledge of preferences of all players, in particular reciprocity functions are common knowledge. Although such an assumption can have some realism in a population of players who know each other well and have experienced frequent interactions over a long period, it does not apply to most experimental data, where subjects interact anonymously for a few periods. Furthermore, the decay in average contribution is obtained by a decline in individual contributions for both types. This requirement seems unnecessarily strong, and does not match individual behavior in voluntary contribution experiments. The experimental data reveals a high variability of individual contributions from period to period (see e.g. Keser & Van Winden, 2000), which is typically not captured in their model. In contrast, our model does not require common knowledge and allows both for increasing and decreasing individual contributions, with the weaker requirement that aggregate contributions cannot

be larger than the initial aggregate moral motivation.

In Klumpp (2010) players are endowed with social preferences. Their utility representation has two additively separable components : material utility and psychological utility. The stage game admits two symmetric Nash equilibria : one where no player contributes to the public good, and one where each player contributes a strictly positive amount. While this dynamic game admits multiple Nash equilibria, the author shows that there is a unique maximal symmetric equilibrium path in pure strategies, for which individual contributions decline. As in Ambrus & Pathak (2010) restricting attention to this particular path is too strong for generating a decline in average contributions, and does not correspond to most available data. More important however, is that the temporal profile of the maximal equilibrium path is not compatible with the pattern typically observed in most experiments on voluntary contributions to a linear public good. In Klumpp's model, the maximal equilibrium path is one where all players contribute all of their endowment up to some date, after which they start lowering their contribution down to a level that is approximately equal to zero. In contrast, average contributions in linear public goods start at a level that is in between half the endowment and the Nash contribution (see Laury & Holt, 2008) and then declines slowly to reach a positive level that is significantly larger than the Nash contribution of the constituent game. In Klumpp's model the average contribution falls very sharply from 100% contribution to nearly 0% contribution over a few periods.

The conclusion of this discussion is that the models proposed by Kandori (2002), Klumpp (2010) and Ambrus & Pathak (2010) have the clear merit to indicate research directions that are worthwhile exploring. But like many pioneering contributions, they rely on unnecessarily strong assumptions to generate the decay of the average contribution and/or their outcomes fit only very roughly with observed data. By contrast, our explanation does not rest on the assumption of common knowledge; it does not depend either on an equilibrium selection argument or on a evolutionary game concept. And the generated outcome accounts for most, if not all, of the empirical regularities observed in the experimental literature.

## 6 Conclusion

Our aim in this paper was to provide a general framework that accounts for the decay of the average contribution observed in most experiments on voluntary contributions to a public good. Each player balances her material utility loss from contributing with her psychological utility loss of deviating from her moral ideal. The central idea of our model is that people's moral motivation is "weak": their judgement about what is the right contribution to a public good can evolve in the course of interactions, depending partly on observed contributions and partly on an intrinsic "moral ideal". The decline of the average contribution is generated by two effects, that presumably can be in conflict. The first one is a downward or selfish-bias which unambiguously reduces slightly each player's contribution below her moral ideal. The second - and novel - effect is the erosion of overcontributions because individuals' moral ideals are weak.

We started by showing that if players behave myopically, *i.e.* they do not take into account the influence of their contribution on others' future moral motivations, the average contribution is non-increasing over time.

The hypothesis of myopic behavior seems to us the most appealing one with respect to the experimental data about subjects' behavior. However, we cannot preclude the fact that some subjects act as farsighted players and try to manipulate others' moral motivation. Therefore, we provided an extension of our basic model, to account for the more general case of farsighted players. Assuming farsighted behavior, we showed that the decline arises if agents value sufficiently the public good ( $\beta$  is large enough) and discount sufficiently the future ( $\sigma$  small enough). The requirement, that under farsighted behavior the discount rate must be small with respect to the value of the public good, justifies our preference for the simpler assumption of myopic behavior for accounting for the decline.

The proposed framework allows for heterogeneity in players' endowment, preferences, and moral ideal. It therefore encompasses a huge variety of individual behaviors. It predicts many observed experimental regularities : over-contributions, heterogeneity of contributions, declining average contributions, final over-contributions and the restart effect.

The proposed model can be interpreted from two, apparently different, behavioral angles: reciprocity and moral motivation. In our model there is a strong link between these two dimensions, because reciprocal behavior is somehow grounded on an internal deliberation process, through which individuals combine their intrinsic motivation to contribute with external pressures in their environment. The hypothesis of weak moral motivation can therefore be thought as a means to rationalize reciprocal behavior.

As a final thought, our model is also related to the endogenous preferences literature (see Bowles, 1998). We believe that, in contrast to models based on heterogeneity of player- types, models based on endogenous preferences are well-adapted to account for various aspects of the behavioral patterns observed in experiments where subjects interact repeatedly.

## Appendix

### A Derivation of the Markov Perfect Equilibrium

In the text, equilibrium decisions for periods  $T$  and  $T-1$  have been given. Moving backward to period  $T-2$ , each agent's decision solves:

$$\max_{x_{iT-2}} \left\{ \begin{array}{l} w_i - x_{iT-2} + \beta_i (x_{iT-2} + x_{-iT-2}) - v_i (x_{iT-2} - M^i(x_i^*, \bar{x}_{T-3})) \\ + \sigma V_{T-1}^i \left( \frac{x_{iT-2} + x_{-iT-2}}{n} \right) \end{array} \right\}.$$

The marginal effects of changing  $x_{iT-2}$  are now as follows:

*i)* As before there are effects on the current utility:

$$-1 + \beta_i - v'_i (x_{iT-2} - M^i(x_i^*, \bar{x}_{T-3})),$$

ii) there are also marginal effects on the discounted indirect utility of period  $T - 1$  :

$$\begin{aligned} & \sigma \left[ \begin{array}{c} -g'_{iT-1} + \beta_i \left( g'_{iT-1} + \sum_{j \neq i} g'_{jT-1} \right) \\ -v'_i \left( x_{iT-1} - M^i \left( x_i^*, \bar{x}_{T-2} \right) \right) \left( g'_{iT-1} - M_2^i \left( x_i^*, \bar{x}_{T-2} \right) \right) \end{array} \right] \frac{\partial \bar{x}_{T-2}}{\partial x_{iT-2}} , \\ &= \frac{\sigma}{n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] , \end{aligned}$$

iii) and finally, there are marginal effects on discounted indirect utility of period  $T$ :

$$\begin{aligned} & \sigma^2 \left[ \begin{array}{c} -g'_{iT} + \beta_i \left( g'_{iT} + \sum_{j \neq i} g'_{jT} \right) \\ -v'_i \left( x_{iT} - M^i \left( x_i^*, \bar{x}_{T-2} \right) \right) \left( g'_{iT} - M_2^i \left( x_i^*, \bar{x}_{T-1} \right) \right) \end{array} \right] \frac{\partial \bar{x}_{T-1}}{\partial x_{iT-2}} \\ &= \sigma^2 \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \frac{\sum_{h=1}^n g'_{hT-1}}{n} * \frac{\partial \bar{x}_{T-2}}{\partial x_{iT-2}} , \\ &= \frac{\sigma^2}{n^2} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=1}^n \theta_h \end{aligned}$$

The first order condition is therefore:

$$-1 + \beta_i - v'_i \left( x_{iT-2} - M^i \left( x_i^*, \bar{x}_{T-3} \right) \right) + \frac{\sigma}{n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \left( 1 + \frac{\sigma}{n} \sum_{h=1}^n \theta_h \right) = 0 .$$

And the dominant response can be expressed again as:

$$\begin{aligned} x_{iT-2} &= -\frac{(1 - \beta)}{v_i} + \frac{\sigma}{vn} \left[ (-1 + \beta) \frac{\theta_i}{n} + \beta \sum_{j \neq i} \frac{\theta_j}{n} \right] \left( 1 + \frac{\sigma}{n} \sum_{h=1}^n \theta_h \right) + M^i \left( x_i^*, \bar{x}_{T-3} \right) , \\ &\equiv g_{iT-2} \left( \bar{x}_{T-3} \right) . \end{aligned}$$

The marginal effects of changing  $x_{iT-3}$  are now as follows:

i) the effects on the current utility are:

$$-1 + \beta_i - v'_i \left( x_{iT-3} - M^i \left( x_i^*, \bar{x}_{T-4} \right) \right) ,$$

ii) there are also marginal effects on the discounted indirect utility of period  $T - 2$  :

$$\begin{aligned} & \sigma \left[ \begin{array}{c} -g'_{iT-2} + \beta_i \left( g'_{iT-2} + \sum_{j \neq i} g'_{jT-2} \right) \\ -v'_i(x_{iT-2} - M^i(x_i^*, \bar{x}_{T-3})) (g'_{iT-2} - M_2^i(x_i^*, \bar{x}_{T-3})) \end{array} \right] \frac{\partial \bar{x}_{T-3}}{\partial x_{iT-3}} , \\ &= \frac{\sigma}{n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] , \end{aligned}$$

iii) and also, there are marginal effects on discounted indirect utility of period  $T - 1$ :

$$\begin{aligned} & \sigma^2 \left[ \begin{array}{c} -g'_{iT-1} + \beta_i \left( g'_{iT-1} + \sum_{j \neq i} g'_{jT-1} \right) \\ -v'_i(x_{iT-1} - M^i(x_i^*, \bar{x}_{T-2})) (g'_{iT-1} - M_2^i(x_i^*, \bar{x}_{T-2})) \end{array} \right] \frac{\partial \bar{x}_{T-2}}{\partial x_{iT-3}} \\ &= \sigma^2 \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \frac{\sum_{h=1}^n g'_{hT-2}}{n} * \frac{\partial \bar{x}_{T-3}}{\partial x_{iT-3}} , \\ &= \frac{\sigma^2}{n^2} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=1}^n \theta_h \end{aligned}$$

iv) and finally, there are marginal effects on discounted indirect utility of period  $T$ :

$$\begin{aligned} & \sigma^3 \left[ \begin{array}{c} -g'_{iT} + \beta_i \left( g'_{iT} + \sum_{j \neq i} g'_{jT} \right) \\ -v'_i(x_{iT} - M^i(x_i^*, \bar{x}_{T-1})) (g'_{iT} - M_2^i(x_i^*, \bar{x}_{T-1})) \end{array} \right] \frac{\partial \bar{x}_{T-1}}{\partial x_{iT-3}} \\ &= \sigma^2 \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \frac{\sum_{h=1}^n g'_{hT-3}}{n} * \frac{\sum_{h=1}^n g'_{hT-2}}{n} * \frac{\partial \bar{x}_{T-3}}{\partial x_{iT-3}} , \\ &= \frac{\sigma^2}{n^3} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \left( \sum_{h=1}^n \theta_h \right)^2 \end{aligned}$$

The first order condition is therefore:

$$-1 + \beta_i - v'_i(x_{iT-3} - M^i(x_i^*, \bar{x}_{T-4})) + \frac{\sigma}{n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \left[ 1 + \frac{\sigma}{n} \sum_{h=1}^n \theta_h + \frac{\sigma^2}{n^2} \left( \sum_{h=1}^n \theta_h \right)^2 \right] = 0$$

And the dominant response can be expressed again as:

$$\begin{aligned} x_{iT-3} &= -\frac{(1 - \beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1 + \beta) \theta_i + \beta \sum_{j \neq i} \theta_j \right] \left[ 1 + \frac{\sigma}{n} \sum_{h=1}^n \theta_h + \frac{\sigma^2}{n^2} \left( \sum_{h=1}^n \theta_h \right)^2 \right] + M^i(x_i^*, \bar{x}_{T-4}) , \\ &\equiv g_{iT-2}(\bar{x}_{T-3}) . \end{aligned}$$

Repeating the logic, and using the notation  $\Lambda = \frac{\sigma}{n} \sum_{h=1}^n \theta_h$ , the dominant strategy  $t$  periods before the last can be written generically:

$$\begin{aligned}
x_{iT-t} &= -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] [1 + \Lambda + \Lambda^2 + \dots + \Lambda^{t-1}] + M^i(x_i^*, \bar{x}_{T-t-1}) , \\
&= -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=0}^{t-1} \Lambda^h + M^i(x_i^*, \bar{x}_{T-t-1}) , \\
&\equiv g_{iT-t}(\bar{x}_{T-t-1}) .
\end{aligned}$$

## B Proof of Proposition 5

Define

$$\begin{aligned}
S_{s+1} &\equiv x_{is+1} - x_{is} < 0 \\
&= -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=0}^{T-s} \Lambda^h + M^i(x_i^*, \bar{x}_s) \\
&\quad - \left\{ -\frac{(1-\beta)}{v_i} + \frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \sum_{h=0}^{T-s-1} \Lambda^h + M^i(x_i^*, \bar{x}_{s-1}) \right\} \\
&= -\frac{\sigma}{v_i n} \left[ (-1+\beta)\theta_i + \beta \sum_{j \neq i} \theta_j \right] \Lambda^{T-s-1} + M^i(x_i^*, \bar{x}_s) - M^i(x_i^*, \bar{x}_{s-1}) .
\end{aligned}$$

Adpating expression (7) for symmetric agents, the contributions of the first period are:

$$x_{i0} = -\frac{(1-\beta)}{v} + \frac{\sigma}{nv} [(-1+n\beta)\theta] \sum_{h=0}^{T-1} \Lambda^h + x^* ,$$

and the contributions afterwards, for  $s = 1, 2, \dots, T$ , are:

$$x_{is} = -\frac{(1-\beta)}{v} + \frac{\sigma}{vn} [(-1+n\beta)\theta] * \sum_{h=0}^{T-s-1} \Lambda^h + (1-\theta)x^* + \theta x_{s-1} .$$

From those pieces of information, one can compute the following speeds of change in

contributions:

$$\begin{aligned}
S_0 &= x_{i1} - x_{i0} \\
&= -\frac{\sigma}{nv} [(-1 + n\beta)\theta] \left[ (1 - \theta)\Lambda^{T-1} - \theta \sum_{h=0}^{T-2} \Lambda^h \right] - \theta \frac{(1 - \beta)}{v} , \\
S_{s+1} &= x_{is+1} - x_{is} = -\frac{\sigma}{nv} [(-1 + n\beta)\theta] \Lambda^{T-s-1} + \theta [x_s - x_{s-1}] \\
&= -\frac{\sigma}{nv} [(-1 + n\beta)\theta] \Lambda^{T-s-1} + \theta S_t .
\end{aligned}$$

It is clear from the above expressions that contributions and speeds depend on the time horizon  $T$ . Thus, from now on we will note those quantities  $x_{is}^T$  and  $S_{t+1}^T$  respectively.

Consider the case where contributions are decreasing, as assumed in Proposition 5. Compare the speed at date 0 of two contribution games that differs only with respect to their time horizon, the first game having  $T$  periods whereas the second one having  $T + p$  periods,  $p > 0$ . The respective initial speeds are given by:

$$\begin{aligned}
S_0^T &= x_{i1}^T - x_{i0}^T = -\frac{\sigma}{2v} [(-1 + n\beta)\theta] \left[ (1 - \theta)\Lambda^{T-1} - \theta \sum_{h=0}^{T-2} \Lambda^h \right] - \theta \frac{(1 - \beta)}{v} < 0 , \\
S_0^{T+p} &= x_{i1}^{T+p} - x_{i0}^{T+p} = -\frac{\sigma}{2v} [(-1 + n\beta)\theta] \left[ (1 - \theta)\Lambda^{T+p-1} - \theta \sum_{h=0}^{T+p-2} \Lambda^h \right] - \theta \frac{(1 - \beta)}{v} < 0 .
\end{aligned}$$

Note that those two speeds are negative numbers because contributions are decreasing by assumption.

Comparing the two speeds, one has:

$$S_0^T - S_0^{T+p} = -\frac{\sigma}{2v} [(-1 + n\beta)\theta] \left[ (1 - \theta)\Lambda^{T-1}(1 - \Lambda^p) + \theta \sum_{h=T-1}^{T+p-2} \Lambda^h \right] < 0 ,$$

or put differently:

$$S_0^T < S_0^{T+p} < 0 ,$$

which means that in absolute value, the longer the horizon, the slower the speed in the first period. The proof is then established recursively. Assume the speed is lower with a longer horizon at any date  $s$  and let us deduce that it will also be lower at date  $s + 1$ . From the expression that links two successive speeds:

$$S_{s+1}^T = -\frac{\sigma}{2v} [(-1 + n\beta)\theta] \Lambda^{T-s-1} + \theta S_s^T ,$$

clearly if  $T$  increases, the first negative term in the right hand side increases (its absolute value decreases), the second and negative term  $S_s^T$  also increases (its absolute value decreases) and therefore  $S_{s+1}^T$  increases, i.e.  $|S_{s+1}^T|$  decreases.
